Positron-emission tomography (PET) is a nuclear medicine functional imaging technique that is used to observe metabolic processes in the body as an aid to the diagnosis of disease. The system detects pairs of gamma rays emitted indirectly by a positron-emitting radionuclide, most commonly fluorine-18, which is introduced into the body on a biologically active molecule called a radioactive tracer.

Positron emission tomography - Wikipedia

Positron emission tomography (PET) is a nuclear medicine functional imaging technique which combines, in a single gantry, a positron emission tomography (PET) scanner and an x-ray computed tomography (CT) scanner, to acquire sequential images from both devices in the same session, which are combined into a single superposed (co-registered) image.

SUMMARY. Positron emission tomography with (18F)2-fluoro-2-deoxy-D-glucose (PET-FDG) is an imaging metabolic technique. PET-FDG is more precise than CT for the evaluation of mediastinal affectation of patients with non-small cell lung cancer, offering a high negative predictive value.

Abstract. The osseous pelvis is a well-recognized site of origin of numerous primary and secondary musculoskeletal tumors. The radiologic evaluation of a pelvic lesion often begins with the plain film and proceeds to computed tomography (CT), or magnetic resonance imaging (MRI) and possibly biopsy.

PCNSL: Conventional CT and MR Imaging. PCNSL often has a characteristic appearance on both CT and MR imaging (). This is due to its hypercellularity, high nuclear/cytoplasmic ratio, disruption of the blood-brain barrier, and its predilection for the periventricular and superficial regions, often in contact with ventricular or meningeal surfaces. 22 â€”25
